Abstract

We show that the formally exact expression for the free energy (with a non-relativistic Hamiltonian) for the correlated metal generates the Poisson equation within the saddle-point approximation for the electric potential, where the charge density automatically includes correlations. In this approximation the problem is reduced to the self-consistent periodical Anderson model (SC-PAM). The parameter of the mixing interaction in this formulation have to be found self-consistently together with the correlated charge density. The factors, calculated by Irkhin, for the mixing interaction, which reflect the structure of the many-electron states of the f -ion involved, arise automatically in this formulation and are quite sensitive to the specific element we are interested in. We also discuss the definitions of the mixing interaction for the mapping from *ab initio* to model calculations.

I. INTRODUCTION

The local density approximation (LDA) to density functional theory (DFT) is working surprisingly well in many cases for which it is expected not to work at all. One of its most important features is that the self-consistent procedure provides a quite accurate distribution of the charge density, calculated from the Kohn-Sham equation¹ which is more accurate than the Poisson equation. It is also important to understand why the form of the potential which has been derived from the theory of a *homogeneous* electron gas with the charge density which includes contributions from the localized electrons (the extreme case of non-homogeneity) works so well. Below we will show that, at least, the Poisson equation can be formulated also in the case of strongly correlated system, where some part of the electrons are either fully or partly localized. On the one hand, physically it is clear that the role played by the localized (core) electrons in the formation of the potential is the screening of the nuclear potential experienced by the conduction electrons (which contribute to the cohesive energy). The localized electrons do not contribute to the cohesive energy and, therefore, the error, coming from an insufficient description of the core electrons is not so essential for the properties derived from a calculation of the total energy at zero temperature. On the other hand, the experience accumulated using the LDA-DFT shows that it fails to describe the properties, which require information about (quasi)localized electrons, like photo-electron spectroscopy experiments, or exchange interaction between localized electrons in magnetic insulators, semiconductors, etc. In these cases, methods either completely based on the field theory or the ones combining the field-theory and DFT, are desirable. The models often used are the Anderson impurity and periodical models and here we will discuss mainly the periodical model. There are two ways for providing methods combining DFT and field theory. The first way is the following. The field operators can be constructed using the functions generated within a LDA-DFT calculation and a correction, constructed from the difference $\mathcal{H}^{int} = \mathcal{H}^{full} - \mathcal{H}^{LDA}$, can be used to correct the electronic structure generated by the initial LDA calculation². The motivation for using the LDA-DFT

basis here is that one can expect compensation by the LDA potential from those part of the self-energy for the conduction electrons, which corresponds to a static random phase approximation³. This way, however, involves complex calculations of the matrix elements of the Coulomb interaction and frequency-dependent magnitudes, like the self-energy, that in practice such calculations are quite hard to perform^{4,5}. The other way, much more often used, is some mapping to the Anderson or Hubbard models. Then, two difficulties arise. *First*, the question about double counting of some of the interactions, and also how to calculate the parameters of the model which is chosen for treating correlations. *Second*, the model calculations often involve a redistribution of spectral weights between low- and high-energy regions and a redistribution of the charge density caused by it. The latter is never taken into account in the model calculations. It is especially important since any redistribution of charge involves a large Coulomb energy. This is especially important when the Anderson model is used for discussing magnetic properties. These properties are determined by the effective exchange integral $\sim V^2/U$ (where V is the mixing and U is the Hubbard on-site repulsion) and, therefore, involves *small* energies. Calculations of this small energy difference, having neglected a possibly greater Coulomb energy, can easily lead to a misinterpretation of the experimental data. It is also important that the mixing interaction is representation dependent and, therefore, for the description of a real system within a model it is important to define clearly what is mixing interaction for that special case. This shows the need for a formulation which allows for a self-consistent calculation of the parameters of the model together with the charge density. Such an opportunity arise in a natural way if one starts with the full Hamiltonian and treat the single-ion Coulomb interactions in some approximation which takes into account the strong local electron correlations. Such a scheme has been suggested earlier⁶, however, the strong electron correlations (SEC) have been treated within the slave-boson technique which at present seems to be unsatisfactory for reasons which we will not discuss here (see, Ref.⁷). Here we will discuss the parameters of the Anderson model within the same scheme, using the definitions of the operators in a non-orthogonal basis set different from Ref.⁶, but coinciding with the ones used in Ref.² and⁸. We have discussed a

way to calculate the single-site Coulomb repulsion parameter, Hubbard U , earlier^{2,8,9}. Here we pay attention mainly to the mixing interaction. The organization of the paper is as follows. In section II we rewrite the Hamiltonian in a non-orthogonal basis set, and construct the many-electron operators. Using a saddle point approximation we get the Poisson equation for the SEC system. In section III we show how the periodical Hubbard-Anderson model appears using the results of section II. In section IV we discuss the mixing parameter entering the model, and in section V we conclude with a discussion.

II. THE POISSON EQUATION IN THE SYSTEM WITH SEC

Here we reformulate the derivation given in Ref.⁶, using the same ideology of separating the electrons in core and valence states. The zero level Hamiltonian is the one considered in Ref.⁶, but within a non-orthogonal basis set and, what is more important, here we avoid the slave-boson technique in favor of the diagram technique from the atomic limit developed in Ref.^{2,8}. Let us consider an ion which has n f -electrons in the ground state. Then, only the transitions $\Gamma_n \rightarrow \Gamma_{n\pm 1}$ will be allowed in the spectrum of excitations while all other transitions like $\Gamma_n \rightarrow \Gamma_{n\pm 2}, \Gamma_{n\pm 3}$, involving a larger number of electrons, will be strongly suppressed by the large energy separation between these states. If the energy of the atomic-like transition $\Delta_2 \equiv E_{\Gamma}^{(n+1)} - E_{\Gamma'}^{(n)}$ between an $(n+1)$ and n -electron state, Γ and Γ' , of the f -ion is much higher than the Fermi energy, ε_F , the number of f -electrons in the ion will be fixed. Indeed, in this limit this upper "single-electron" level is empty while the lower one, even if it forms a band, will be fully filled. In the rare earth elements the populated part of the f -spectral density corresponding to the transitions $\Delta_1 \equiv E_{(n)} - E_{(n-1)}$ is much below ε_F (except for Ce, and perhaps Sm). It can be also much below the bottom of the conduction-electron bands. When an orbital has such a low energy, the mixing interaction, as well as overlap between these core-like levels and conduction electrons are negligible¹⁰. This physical picture exactly corresponds to the type of *ab initio* calculation where the f -electrons are kept in the core. One can use the many-electron functions for the description of

the ground state of an ion from DFT-LDA-based calculations too. All electrons in this case experience the same potential. As has been shown in Ref.⁸, this picture is valid when the energy of the upper transition, $\Delta_2 = E_{(n+1)} - E_n$, is much above Fermi energy. However, the photo-electron spectroscopy experiments show that even in rare earth elements, for which this picture seems to be most appropriate, the level Δ_2 is sometimes only slightly above ε_F ¹¹. Therefore, due to mixing interaction and, possibly, hopping, a band with mixed f - and conduction electron states¹² can be formed. As discussed in details in Ref.⁸, this leads to shifts of spectral weights from integer values and a violation of the single-electron picture. These spectral weights, therefore, must enter the expression for the charge density in the Poisson equation. Besides, they control the strength of the mixing and hopping. Let us derive the Poisson equation which contains the information about these spectral weights and is valid not only for zero temperature. Here, we will not consider the formation of phonons and scattering processes which involve them, nor plasmons.

A. The Hamiltonian in a Non-Orthogonal Basis Set

An orthogonalization procedure of the wave-functions belonging to different ions leads to a coupling of the states. This makes it difficult to separate the strongest single-site interactions. Therefore, the local strong interactions between f -electrons can most easily be taken into account in the *non-orthogonal* site representation. For this reason we will, to some extent, use the technique developed previously² (below referred to as I). The delocalized electrons are treated within the weak-coupling perturbation theory (WCPT), while the localized (or semi-localized) within the strong-coupling theory (SCPT), see I. In order to introduce, for the f -operators (and other core electrons), the many-electron representation we rewrite the field operator, $\hat{\psi}_\sigma(\mathbf{r})$, in the jL -representation

$$\hat{\psi}_\sigma(\mathbf{r}) = \int d\mathbf{q} e^{-i\mathbf{q}\cdot\mathbf{r}} \phi_{jL}(\mathbf{r}) a_{jL}, \quad (1)$$

$$a_{jL} = [(1 - \delta_{L,\mu})c_{jL} + \delta_{L,\mu}f_{j\mu}]. \quad (2)$$

Here, $j \equiv R_j$ is the site, $L \equiv (l, m_l, s = 1/2, \sigma)$, l is the orbital moment, m_l is its projection to the z -axis, s is electron spin and σ its projection to the same axis μ indicates localized electrons. In Eq.(2) we have separated all electrons to two classes: core electrons, $f_{j\mu}$, which either remain fully localized in solids, or only partly delocalized, and delocalized electrons, c_{jL} , which will be described in $\mathbf{k}$ -space in regular crystals. Since the essential part of the work to be done concerns the localized electrons, it is reasonable to formulate the approach in the site representation first. The basis functions $\phi_{jL}(\mathbf{r})$ are in general not orthogonal to each other,

$$\int d\mathbf{r} \phi_{jL}^*(\mathbf{r}) \phi_{j'L'}(\mathbf{r}) = \mathcal{O}_{jL,j'L'}. \quad (3)$$

therefore, from $\{\psi_\sigma(\mathbf{r}), \psi_{\sigma'}^\dagger(\mathbf{r}')\} = \delta(\mathbf{r} - \mathbf{r}')\delta_{\sigma\sigma'}$, we see that

$$\{a_{jL}, a_{j'L'}^\dagger\} = \mathcal{O}_{jL,j'L'}^{-1}, \quad (4)$$

where $\mathcal{O}_{jL,j'L'}^{-1}$ is the $(jL, j'L')$ -matrix element of the inverse of the overlap matrix $\mathbf{O}$.

The full Hamiltonian is

$$\begin{aligned} \mathcal{H} = & \int d\mathbf{r} \psi_\sigma^\dagger(\mathbf{r}) \left[\frac{p^2}{2m} - \sum_j \frac{Z_j e^2}{|\mathbf{r} - \mathbf{R}_j|} - C_\infty \right] \psi_\sigma(\mathbf{r}) + \mathcal{H}_{nn} \\ & + \frac{1}{2} \int d\mathbf{r} d\mathbf{r}' \psi_\sigma^\dagger(\mathbf{r}) \psi_\sigma(\mathbf{r}) v(\mathbf{r} - \mathbf{r}') \psi_{\sigma'}^\dagger(\mathbf{r}') \psi_{\sigma'}(\mathbf{r}'), \end{aligned} \quad (5)$$

$$\mathcal{H}_{nn} = \sum_j \frac{Z_i Z_j e^2}{|\mathbf{R}_i - \mathbf{R}_j|}, \quad (6)$$

where C_∞ is the infinite constant $\int d\mathbf{r} d\mathbf{r}' \delta(\mathbf{r} - \mathbf{r}') v(\mathbf{r} - \mathbf{r}') \sum_{\sigma'} \delta_{\sigma\sigma'}$ which arose when we transformed $\psi_1^\dagger \psi_2^\dagger v(1, 2) \psi_2 \psi_1$ into $\psi_1^\dagger \psi_1 v(1, 2) \psi_2^\dagger \psi_2$. We omit this constant below, since it does not influence the physics. Let us rewrite the Hamiltonian in the representation using the functions $\phi_{jL}(\mathbf{r})$ (which can also be defined in different ways and we shall discuss it later). Using the expansion in Eq.(1) inserted into Eq.(5) gives

$$\begin{aligned} \mathcal{H} = & \mathcal{H}_{nn} + \sum_{j_2 L_2, j_3 L_3} h_{j_2 L_2, j_3 L_3}^0 a_{j_2 L_2}^\dagger a_{j_3 L_3} \\ & + \left[\frac{1}{2} \sum_{\{jL\}} v_{j_2 L_2, j_3 L_3, j_4 L_4, j_5 L_5} a_{j_2 L_2}^\dagger a_{j_5 L_5} a_{j_3 L_3}^\dagger a_{j_4 L_4} \right]. \end{aligned} \quad (7)$$

Here

$$h_{j_2 L_2, j_3 L_3}^0 \equiv (j_2 L_2 | \left[\frac{p^2}{2m} - \sum_j \frac{Z_j e^2}{|\mathbf{r} - \mathbf{R}_j|} \right] | j_3 L_3), \quad (8)$$

Now we assume that the nuclei are in fixed positions and separate the part of the Hamiltonian which contains on-site interactions between electrons that are treated as core electrons

$$\begin{aligned} \mathcal{H}^{ion} = \sum_j \mathcal{H}_j^{ion} = \sum_j \left\{ \sum_{\mu_2, \mu_3} h_{j\mu_2, j\mu_3}^0 f_{j\mu_2}^\dagger f_{j\mu_3} \right. \\ \left. + \frac{1}{2} \sum_{\{\mu\}} v_{j\mu_2, j\mu_3, j\mu_4, j\mu_5} a_{j\mu_2}^\dagger a_{j\mu_5} a_{j\mu_3}^\dagger a_{j\mu_4} \right\}. \end{aligned} \quad (9)$$

The single-site part of the problem and the rest will be treated in different approximations. We want to use Hubbard operators that are usually introduced in such a way that they diagonalize the single-ion Hamiltonian

$$H_j^{ion} |j, \Gamma_n\rangle = E_{j\Gamma_n} |j, \Gamma_n\rangle, \quad (10)$$

$$X_j^{\Gamma_n \Gamma_m} \equiv |j, \Gamma_n\rangle \langle j, \Gamma_m|. \quad (11)$$

Let us now discuss how to construct them.

B. The Hubbard Operators in Terms of Fermions

We are not able to diagonalize the full Hamiltonian exactly, unless for certain model calculations, and we have to use some approximation. In order to ensure that the ground-state wave function fulfills Hund's rules, we will follow the technique by Irkhin¹³, who translated the Racah technique, used in atomic spectroscopy¹⁴ for the wave functions, into the operator language. Although this issue has been discussed in Refs.^{15,2}, we find the definition used not fully satisfactory and in need of a slight modification. For this reason we discuss the definition of the many-electron operators and, correspondingly, the connection between the Hubbard operators and the many-electron creation and annihilation operators and the modification needed. The creation operator for a group of n equivalent electrons (say, in an f -shell) in the many-electron state $|\Gamma_n\rangle = A_{\Gamma_n}^\dagger |0\rangle$ in Irkhin's definition has the form

$$A_{\Gamma_n}^\dagger = \frac{1}{\sqrt{n}} \sum_{\mu, \Gamma_{n-1}} G_{\Gamma_{n-1}}^{\Gamma_n} C_{\Gamma_{n-1}, \mu}^{\Gamma_n} f_\mu^\dagger A_{\Gamma_{n-1}}^\dagger. \quad (12)$$

Here $G_{\Gamma_{n-1}}^{\Gamma_n}$ are the fractional parentage coefficients, which do not depend on the momentum projections (if $n \leq 2$, $G = 1$ and the squared coefficient, $(G_{\Gamma_{n-1}}^{\Gamma_n})^2$, measures the fracture of the state $|\Gamma_{n-1}\rangle$ in $|\Gamma_n\rangle$); $C_{\Gamma_{n-1}, \mu}^{\Gamma_n}$ are the Clebsch-Gordan coefficients,

$$C_{\Gamma_{n-1}, \mu}^{\Gamma_n} \equiv C_{L_n M_L^{(n-1)}, l m_l}^{L_n M_L^{(n)}} C_{S_{n-1} M_S^{(n-1)}, 1/2, \sigma}^{S_n M_S^{(n)}}, \quad (13)$$

where $L_n, M_L^{(n)}, S_n, M_S^{(n)}$ are the orbital moment, its projection, spin moment and its projection for the n -electron configuration $|\Gamma_n\rangle$. In order to be able to calculate the commutation relations between the conduction electrons and the Hubbard operators (H-operators) as well as between the H-operators themselves, we have to express them in terms of Fermion operators. We have to provide the correct commutation relations for H-operators, belonging to the same site

$$[X^{\gamma\Gamma}, X^{\Lambda\chi}]_\pm = \delta^{\Gamma\Lambda} X^{\gamma\chi} \pm \delta^{\chi\gamma} X^{\Lambda\Gamma}. \quad (14)$$

If we try to define an H-operator in the form of a product of the operators A , i.e. $X^{\gamma\Gamma} = A_\gamma^\dagger A_\Gamma$, we should get zero if we multiply by $X^{\gamma\Gamma_n} X^{\Lambda_m\chi}$ for $n \neq m$. This should be provided by the fact, that for the Fermion operators $f^2 = (f^\dagger)^2 = 0$. However, the product $A_{\Gamma_n} A_{\Lambda_m}^\dagger \neq 0$, if $n < m$, because the operators A_{Γ_n} do not contain information about non-filled orbitals of the shell. The operators A_{Γ_n} do not provide the orthogonality of the states with different number of electrons in shell. The recipe suggested in Ref.¹⁵ is to define new operators as follows

$$\tilde{A}_{\Gamma_n}^\dagger = A_{\Gamma_n}^\dagger \prod_\mu (1 - \hat{n}_\mu), \quad \tilde{A}_{\Gamma_n} = \prod_\mu (1 - \hat{n}_\mu) A_{\Gamma_n}. \quad (15)$$

The product should run over all non-filled orbitals. Let us consider, for example, the two-electron state composed of f -states, $|\Gamma_2\rangle = |L = 5, M_L^{(2)} = 4, S = 1, M_S^{(2)} = 0\rangle$. Then, the operator

$$A_{\Gamma_n}^\dagger = \sum_{m_1 m_2 \sigma_1 \sigma_2} C_{3m_1, 3m_2}^{5,4} C_{1/2, \sigma_1; 1/2, \sigma_2}^{1,0} f_{3m_1; 1/2, \sigma_1}^\dagger f_{3m_2; 1/2, \sigma_2}^\dagger \quad (16)$$

combines three terms (for briefness below we omit indices $l = 3$ and spin $s = 1/2$:

$$A_{\Gamma_2}^\dagger = \alpha[f_{3\uparrow}^\dagger f_{1\downarrow}^\dagger + \gamma f_{2\uparrow}^\dagger f_{2\downarrow}^\dagger + f_{1\uparrow}^\dagger f_{3\downarrow}^\dagger] \quad (17)$$

with $\alpha = \sqrt{5/253}, \gamma = 27/\sqrt{15}$. Now, we have to multiply this by the product of the factors $(1 - \hat{n}_\mu)$, where μ runs over all empty orbitals. From this a problem is apparent: the different terms of the combinations of Clebsch-Gordan coefficients involve *different* orbitals and, therefore, it is impossible to choose a single factor which includes all empty orbitals for each term in the sum. Therefore, *each term* of the sum must be supplemented with its own factor. In this particular example the new many-electron operator should be defined as follows

$$\begin{aligned} \tilde{A}_{\Gamma_2}^\dagger = \alpha & \left[f_{3\uparrow}^\dagger f_{1\downarrow}^\dagger \prod_{m_1 \neq 3} (1 - \hat{n}_{m_1\uparrow}) \prod_{m_2 \neq 1} (1 - \hat{n}_{m_2\downarrow}) + \gamma f_{2\uparrow}^\dagger f_{2\downarrow}^\dagger \prod_{m_1 \neq 2} (1 - \hat{n}_{m_1\uparrow}) \prod_{m_2 \neq 2} (1 - \hat{n}_{m_2\downarrow}) \right. \\ & \left. + f_{1\uparrow}^\dagger f_{3\downarrow}^\dagger \prod_{m_1 \neq 1} (1 - \hat{n}_{m_1\uparrow}) \prod_{m_2 \neq 3} (1 - \hat{n}_{m_2\downarrow}) \right] \equiv \alpha[\tilde{A}_{\Gamma_2(3\uparrow,1\downarrow)}^\dagger + \gamma \tilde{A}_{\Gamma_2(2\uparrow,2\downarrow)}^\dagger + \tilde{A}_{\Gamma_2(1\uparrow,3\downarrow)}^\dagger]. \end{aligned} \quad (18)$$

Obviously, in a general case, when we construct the operator $\tilde{A}_{\Gamma_2}^\dagger$, *each term* in the sum should be multiplied by the product of the factors $(1 - \hat{n}_{m\sigma})$ corresponding to this term, where the set of $\{m\sigma\}$ includes only those orbitals which are not included in the product of the f -operators in the corresponding term of the Clebsch-Gordan sum. Let us denote this product $\bar{\Pi}$, where the bar over Π means that it contains only complementary orbitals. In I we used the *orbital representation*, where each H-operator contains only one term, containing n creation f -operators for the n -electron state which is multiplied by the product $\bar{\Pi}$. We will call it *elementary operator*. In the case of Eq.(18) these operators are $\tilde{A}_{\Gamma_2(3\uparrow,1\downarrow)}^\dagger, \tilde{A}_{\Gamma_2(2\uparrow,2\downarrow)}^\dagger, \tilde{A}_{\Gamma_2(1\uparrow,3\downarrow)}^\dagger$. We can, therefore, make the statement that any operator of a state in a central field (i.e. of the Clebsch-Gordan combination type) or in a crystal field, can be represented as a sum of elementary operators with the coefficients, which are dictated by the symmetry of the surrounding of the ion. Since the construction of the state in central field within the Racah technique is recursive, i.e. the n -electron state is composed

of $(n-1)$ -electron states and one-electron states, the $(n-1)$ -one is made of the combination of $(n-2)$ -and one-electron states, and so on, this statement needs proof. Let us start with a many-electron operator, describing one localized electron in orbital 1. The electron state has the form $f_1^\dagger \prod_{\nu \neq 1} (1 - \hat{n}_\nu)$. In order to construct the state, which contain two electrons localized in the states 1 and 2, we have to multiply this operator by $f_2^\dagger$ from the left-hand side. Since $f_2^\dagger (1 - \hat{n}_2) = f_2^\dagger$, all extra factors $(1 - \hat{n}_\nu)$ are automatically projected out and we are back at Eq.(12). Therefore, each step to a higher number electron operator will be started again with Eq.(12). This means that the factors $\bar{\Pi}$ should be added in each term of the sum in the last step only. Thus, the Hubbard operator can be written in the form

$$X^{\gamma\Gamma} = \tilde{A}_\gamma^\dagger \tilde{A}_\Gamma, \quad (19)$$

where each elementary operator entering the sum for the operator $\tilde{A}_\gamma^\dagger$ contains the projecting product $\bar{\Pi}_\gamma^{(i)}$. The same is valid for $\tilde{A}_\Gamma$ and $\bar{\Pi}_\Gamma^{(j)}$. Then, we can represent each $f_{j\mu}$ -operator in any place where we meet it, particularly, in the Hamiltonian, in terms of H-operators $X_j^a \equiv X_j^{a(\gamma,\Gamma)} \equiv X_j^{[\gamma,\Gamma]}$.

$$f_{j\mu} \equiv (f_\mu)^a X_j^a. \quad (20)$$

Here, repeated indices are summed over. The H-operators can also be written in the Hubbard form $X_j^{[\gamma,\Gamma]} \equiv |\mathbf{R}_j, n, \gamma\rangle \langle \mathbf{R}_j, n+1, \Gamma|$ or in terms of products of Fermion operators as discussed above (here $|\mathbf{R}_j, n, \gamma\rangle$ and $|\mathbf{R}_j, n+1, \Gamma\rangle$ are many-electron n - and $(n+1)$ -particle states). Using the definition of the many-electron operators and the Hubbard operators in terms of Fermion operators one can calculate all commutation relations between the conduction electrons operators and the Hubbard operators²,

$$\{c_{jL}, X_{j'}^{\bar{a}}\} = O_{jL,j'\nu}^{-1} f_\nu^b \varepsilon_\xi^{b\bar{a}} Z_{j'}^\xi. \quad (21)$$

Here, a, b denote the Fermi-like transitions from the n - to $(n+1)$ -electron state ($a = a(\Gamma_n, \Gamma_{n+1})$), $\bar{a}$ denotes the inverse transition ($\bar{a} = \bar{a}(\Gamma_{n+1}, \Gamma_n)$), $\xi = \xi(\Gamma_n, \Gamma'_n)$ and $\varepsilon_\xi^{b\bar{a}}$ are the structure constants of the algebra for the Hubbard operators,

$$\{X_j^b, X_{j'}^{\bar{a}}\} = \varepsilon_\xi^{b\bar{a}} Z_{j'}^\xi, \quad \{X_j^b, Z_{j'}^\xi\} = \varepsilon_a^{b\xi} X_{j'}^a, \quad \{X_j^{\bar{b}}, Z_{j'}^\xi\} = \varepsilon_{\bar{a}}^{\bar{b}\xi} X_{j'}^{\bar{a}}. \quad (22)$$

The summation over repeating indices is implied. A Bose-like transition is denoted as Z^ξ and a diagonal Bose-like operator is denoted as h_j^Γ , $h_j^\Gamma \equiv Z_j^{\xi(\Gamma, \Gamma)}$.

C. The Field for the Electric Potential and the Poisson Equation

Let us introduce the Fourier-component of the charge density for the nuclei in the point $\mathbf{R}_\alpha$ with the charge Z_α :

$$\hat{\rho}_n(\mathbf{q}) = \sum_j Z_j e^{i\mathbf{q} \cdot \mathbf{R}_j}. \quad (23)$$

Then, the interaction between the nuclei is

$$\mathcal{H}_{nn}^{coul} = \frac{1}{2} \sum_{jj'} \frac{Z_j Z_{j'} e^2}{|\mathbf{R}_j - \mathbf{R}_{j'}|} = \int d\mathbf{q} \hat{\rho}_i(\mathbf{q}) \frac{4\pi e^2}{q^2} \hat{\rho}_i(-\mathbf{q}). \quad (24)$$

The interaction between electrons and nuclei,

$$\begin{aligned} \mathcal{H}_{en}^{coul} &= - \sum_j \int d\mathbf{r} \hat{\rho}_e(\mathbf{r}) \frac{Z_j e^2}{|\mathbf{R}_j - \mathbf{r}|} \\ &= - \int d\mathbf{q} \hat{\rho}_e(\mathbf{q}) \frac{4\pi e^2}{q^2} \hat{\rho}_n(-\mathbf{q}), \end{aligned} \quad (25)$$

contains the electrons which are localized to the same nucleus, or to other ones, and those which are in a mixed state. The interaction of the localized electrons with their own nucleus is

$$\begin{aligned} &- \sum_j \int d\mathbf{r} \frac{Z_j e^2}{|\mathbf{r} - \mathbf{R}_j|} \phi_\nu^*(\mathbf{r} - \mathbf{R}_j) \phi_\mu(\mathbf{r} - \mathbf{R}_j) (f_\nu^\dagger f_\mu)^\xi Z_j^\xi \\ &= - \int d\mathbf{q} \frac{4\pi e^2}{q^2} \sum_j Z_j S_j^\xi(\mathbf{q}) Z_j^\xi, \end{aligned} \quad (26)$$

where S_j^ξ is the form-factor of the ion, which takes into account the contribution of the orbitals ν and μ into the transition ξ

$$\mathcal{O}_j^\xi(q) = \int dr e^{iqr} \phi_{j\nu}^*(r) \phi_{j\mu}(r) (f_\nu^\dagger f_\mu)^\xi \quad (27)$$

and the index j in $\phi_{j\mu}(\mathbf{r})$ denotes affiliation of this function to the ion on $\mathbf{R}_j$. This term is included to the Hamiltonian for the ion in this point. The term

$$\begin{aligned}
& - \sum_{jn} \int d\mathbf{r} \frac{Z_j e^2}{|\mathbf{r} - \mathbf{R}_j|} (1 - \delta_{jn}) \phi_\nu^*(\mathbf{r} - \mathbf{R}_n) \\
& \times \phi_\mu(\mathbf{r} - \mathbf{R}_n) (f_\nu^\dagger f_\mu)^\xi Z_n^\xi \\
& = - \int d\mathbf{q} \frac{4\pi e^2}{q^2} \sum_{j \neq n} [Z_j e^{-i\mathbf{q} \cdot \mathbf{R}_j} \mathcal{O}_n^\xi(\mathbf{q}) Z_n^\xi e^{i\mathbf{q} \cdot \mathbf{R}_n}]
\end{aligned} \tag{28}$$

describes the interaction of localized electrons belonging to one ion with a nucleus of another ion. Then, the operator of an effective density of ions can be written as

$$\hat{\rho}_i(\mathbf{q}) = \sum_j [Z_j - \sum_\xi \mathcal{O}_j^\xi(\mathbf{q}) Z_j^\xi] e^{i\mathbf{q} \cdot \mathbf{R}_j} \tag{29}$$

and the interaction between all nuclei which are screened by their electrons is

$$\frac{1}{2} \int d\mathbf{q} \hat{\rho}_i(\mathbf{q}) \frac{4\pi e^2}{q^2} \hat{\rho}_i(-\mathbf{q}) - \mathcal{H}_D. \tag{30}$$

Here, $\mathcal{H}_D$ takes into account the terms which are double counted in the first term, since there is no interaction of the ion with itself

$$\begin{aligned}
\mathcal{H}_D &= \frac{1}{2} \sum_j \int d\mathbf{q} [Z_j - \sum_\xi \mathcal{O}_j^\xi(\mathbf{q}) Z_j^\xi] \frac{4\pi e^2}{q^2} [Z_j \\
& - \sum_\xi \mathcal{O}_j^\xi(\mathbf{q}) Z_j^\xi].
\end{aligned} \tag{31}$$

The terms of this interaction at small $\mathbf{q}$, as well as $\mathcal{H}_D$ itself, diverge. This is the standard problem of screening.

All other electrons belong either to the class of the transitions between different ions, or to a mixed state between conduction-electron and localized electrons, or to the conduction electrons. The operator of the charge density, $\hat{\rho}_\mathbf{r}(\mathbf{q})$, of these remaining electrons can be written as follows

$$\begin{aligned}
\hat{\rho}_\mathbf{r}(\mathbf{q}) &= \sum_{jLj'L'} \mathcal{O}_{jLj'L'}(\mathbf{q}) c_{jL}^\dagger c_{j'L'} \\
& + \sum_{jLj'\mu'} \mathcal{O}_{jLj'\mu'}(\mathbf{q}) (f_{\mu'}^\dagger)^a c_{jL}^\dagger X_{j'}^a + \mathcal{O}_{j\mu j'L'}(\mathbf{q}) (f_\mu^\dagger)^{\bar{a}} X_j^{\bar{a}} c_{j'L'} \\
& + (1 - \delta_{jj'}) \mathcal{O}_{j\mu j'\mu'}(\mathbf{q}) (f_\mu^\dagger)^{\bar{a}} (f_{\mu'})^b X_j^{\bar{a}} X_{j'}^b
\end{aligned} \tag{32}$$

The matrices $\mathcal{O}(\mathbf{q})$ are defined as

$$\mathcal{O}_{jLj'L'}(\mathbf{q}) = \int d\mathbf{r} e^{i\mathbf{q}\cdot\mathbf{r}} \phi_{jL}^*(\mathbf{r}) \phi_{j'L'}(\mathbf{r}). \quad (33)$$

Thus, we obtain the Hamiltonian in the many-electron representation

$$\mathcal{H} = \mathcal{H}_0 + (\mathcal{H}^{coul} + T), \quad (34)$$

where T is the kinetic energy, and the zero Hamiltonian is

$$\mathcal{H}_0 = \mathcal{H}_0^X + \mathcal{H}_0^c = \sum_{j\Gamma} E_{j\Gamma} h_j^\Gamma + \sum h_{jL,j'L'}^{0c} c_{jL}^\dagger c_{j'L'}. \quad (35)$$

Here $\mathcal{H}_0^X$ describes the electrons treated as core electrons when the interaction between the ions and all other electrons is switched off

$$\begin{aligned} E_{j\Gamma} = (j, \Gamma | & \sum_{i \in \mathbf{R}_j} \frac{p_i^2}{2m} - \sum_{i \in \mathbf{R}_j} \frac{Z_j e^2}{|\mathbf{R}_j - \mathbf{r}_i|} \\ & + \frac{1}{2} \sum_{i, i' \in \mathbf{R}_j} \frac{Z_j e^2}{|\mathbf{r}_i - \mathbf{r}_{i'}|} |j, \Gamma), \end{aligned} \quad (36)$$

and the function $|j, \Gamma\rangle$ is a many-electron wave-function. The Hamiltonian of the conduction electrons, $\mathcal{H}_0^c$, describes the electrons in the field of the unscreened nuclei. This will be supplemented with the self-consistent field from the electrons. The kinetic energy of the electrons which belong to one site is taken into account, while the part T of it, which is proportional to $\hat{\rho}_{\mathbf{r}}(\mathbf{q})$, is not. We will treat this part of the kinetic energy as a perturbation. Thus, the full Coulomb interaction can be written as follows

$$\begin{aligned} & \frac{1}{2} \int d\mathbf{q} [\hat{\rho}_i(\mathbf{q}) - \hat{\rho}_{\mathbf{r}}(\mathbf{q})] \frac{4\pi e^2}{q^2} [\hat{\rho}_i(\mathbf{q}) - \hat{\rho}_{\mathbf{r}}(\mathbf{q})] \\ & \equiv \frac{1}{2} \int d\mathbf{q} \hat{\rho}_{\mathbf{q}} \frac{4\pi e^2}{q^2} \hat{\rho}_{\mathbf{q}}. \end{aligned} \quad (37)$$

The partition function, written in the standard form, is

$$\begin{aligned} Z &= Tr \exp[-\beta(\mathcal{H} - \mu N)] \\ &= Z_0 \frac{1}{Z_0} Tr \{ \exp[-\beta \mathcal{H}_0] \mathcal{T}_\tau \exp[-\int_0^\beta d\tau \mathcal{H}_{int}(\tau)] \} \\ &\equiv Z_0 \cdot \langle \mathcal{T}_\tau \exp[-\int_0^\beta d\tau \mathcal{H}_{int}(\tau)] \rangle^{(0)} \end{aligned} \quad (38)$$

Let us write the part $\mathcal{H}_{\rho\rho}^{coul}$ of $\mathcal{H}_{int}$ in the Fourier transformed form, Eq.(32). Then, we introduce the Gaussian functional integral

$$1 = \int D\varphi_{\mathbf{q}}(\tau) \exp\left[-\int_0^\beta \frac{d\tau}{8\pi} \int d\mathbf{q} q^2 \varphi_{\mathbf{q}}(\tau) \varphi_{-\mathbf{q}}(\tau)\right] \quad (39)$$

under the trace of the partition function. We make the shift

$$\varphi_{\mathbf{q}}(\tau) \rightarrow \varphi_{\mathbf{q}}(\tau) + i\frac{4\pi e}{q^2} \hat{\rho}_{\mathbf{q}}, \quad (40)$$

in this Gaussian integral. This allows us to rewrite the Coulomb interaction in terms of interaction of electrons with the random field $\varphi_{\mathbf{q}}(\tau)$. This shift generates the term $(-\mathcal{H}_{\rho\rho}^{coul})$ which cancels the $\mathcal{H}_{\rho\rho}^{coul}$ in the $\mathcal{H}_{int}$ but adds the term

$$-\frac{ie}{2} \int_0^\beta d\tau \int d\mathbf{q} [\varphi_{\mathbf{q}}(\tau) \hat{\rho}_{-\mathbf{q}}(\tau) + \hat{\rho}_{\mathbf{q}}(\tau) \varphi_{-\mathbf{q}}(\tau)]. \quad (41)$$

Note that, although the f -orbitals of the same site are orthogonalized, the $\mathbf{q} \neq 0$ -components of the overlap matrix have non-zero values and, therefore, non-diagonal transitions $\xi \neq [\Gamma, \Gamma]$ enter the expression for $\mathbf{q}$ -component of the charge density. Thus, we have to work with the following expression for the partition function

$$\begin{aligned} \frac{Z}{Z_0} &= \int D\varphi_{\mathbf{q}}(\tau) \exp\left[-\int_0^\beta d\tau \int d\mathbf{q} \frac{q^2}{8\pi} \varphi_{\mathbf{q}}(\tau) \varphi_{-\mathbf{q}}(\tau)\right] \\ &\times \exp[-\beta \mathcal{F}[\varphi_{\mathbf{q}}(\tau), \varphi_{-\mathbf{q}}(\tau)]], \end{aligned} \quad (42)$$

where

$$\begin{aligned} \mathcal{F}[\varphi_{\mathbf{q}}(\tau), \varphi_{-\mathbf{q}}(\tau)] &\equiv -\frac{1}{\beta} \ln \langle \mathcal{T}_\tau \exp\left[-\int_0^\beta d\tau \int d\mathbf{q} (T_{\mathbf{q}} - \mathcal{H}_\rho \right. \\ &\quad \left. - \mathcal{H}_D)\right] \rangle^{(0)}, \end{aligned} \quad (43)$$

$$T_{\mathbf{q}} \equiv \left[\frac{\hat{p}^2}{2m} \right]_{\mathbf{q}} \rho_{\mathbf{r}}(\mathbf{q}) \quad (44)$$

$$\begin{aligned} \mathcal{H}_\rho &= \frac{1}{2} \int d\mathbf{q} [(ie\varphi_{\mathbf{q}}(\tau) - \mu) \hat{\rho}_{-\mathbf{q}}(\tau) + \hat{\rho}_{\mathbf{q}}(\tau) \\ &\quad \times (ie\varphi_{-\mathbf{q}}(\tau) - \mu)], \end{aligned} \quad (45)$$

$$\mathcal{H}_i^0 = \mathcal{H}_0^c + \mathcal{H}_0^X. \quad (46)$$

Here, we have used the fact that the fields $\varphi_{\mathbf{q}}(\tau)$ commute with any operator. The function $\mathcal{F}$ is written in the form usually used for the cumulant expansion.

Since both the mixing interaction and overlap matrices are non-zero, a part of the charge is in the mixed cf -states. Besides, the f -subsystem is described in terms of *non-linear* X -operators. For these reasons we cannot describe the full contribution from the term $\mu\hat{N}$ in the zero Hamiltonian. The field $\varphi_{\mathbf{q}}(\tau)$ can be interpreted as the field for the electrical potential which is generated by Coulomb interaction. If we put $e = 0$ the system does not have charged particles and, therefore, there are no contribution to the partition function from this field. At $e \neq 0$ in a non-homogeneous system an average charge density is not equal to zero, and, therefore, the expectation value $\langle\varphi_{\mathbf{q}}(\tau)\rangle_{\varphi}$ is non-zero too. Taking the functional derivative of the free energy, we find that the saddle-point approximation generates the Poisson equation for this field

$$\begin{aligned}\frac{\delta F}{\delta\varphi_{-\mathbf{q}}(\tau)} &\equiv \frac{\delta(-\mathcal{T} \ln Z)}{\delta\varphi_{-\mathbf{q}}(\tau)} \\ &= -\frac{q^2}{8\pi}\langle\varphi_{\mathbf{q}}(\tau)\rangle_{\varphi} + \frac{ie}{2}\langle\hat{\rho}_{\mathbf{q}}(\tau)\rangle_{\varphi} = 0.\end{aligned}\quad (47)$$

The static part of the field of the electrical potential $\Phi(\mathbf{r})$ is connected with the field $\langle\varphi\rangle$ as follows

$$\Phi(\mathbf{r}) \equiv \lim_{\tau \rightarrow -0} i\langle\varphi(\mathbf{r}, \tau)\rangle_{\varphi} = i\langle\varphi(\mathbf{r}, 0)\rangle_{\varphi}.\quad (48)$$

Thus, we have the Poisson equation for the electric field $\Phi(\mathbf{r})$,

$$\nabla^2\Phi(\mathbf{r}) = -4\pi\langle\hat{\rho}_{\mathbf{q}}(0)\rangle_{\varphi},\quad (49)$$

where the charge density is the difference between the densities of the delocalized electrons and "soft" ion (where the polarization of the ion and excitations are allowed).

III. THE SELF-CONSISTENT HUBBARD-ANDERSON MODEL

Since the charge density, $\langle\hat{\rho}_{\mathbf{q}}(0)\rangle_{\varphi}$, contains expectation values $\langle c_{jL}^{\dagger}c_{j'L'}\rangle$, $\langle c_{jL}^{\dagger}X_{j'}^a\rangle$, $\langle X_{j'}^a c_{jL}\rangle$, $\langle X_{j'}^a X_{j'}^b\rangle$, we need expressions for them. Since the field $\varphi(\mathbf{r}, \tau)$ contains the av-

erage static field and deviations of it

$$\varphi(\mathbf{r}, \tau) = \frac{1}{i} \Phi(\mathbf{r}) + \delta\varphi(\mathbf{r}, \tau), \quad (50)$$

it is reasonable to start with the approximation $i\varphi_{\mathbf{q}}(\tau)_{\varphi} \rightarrow i\langle\varphi_{\mathbf{q}}(0)\rangle_{\varphi} \rightarrow \Phi(\mathbf{q})$, and to neglect the fluctuations of this field. Then, we obtain the following saddle-point Hamiltonian

$$\begin{aligned} \tilde{\mathcal{H}}_0 = & \int d\mathbf{q} \, q^2 \Phi(\mathbf{q}) \Phi(-\mathbf{q}) \\ & + \sum (h_{jL,j'L'} - \mu \mathcal{O}_{jL,j'L'}) c_{jL}^{\dagger} c_{j'L'} \\ & + \sum (E_{j\Gamma}^{(n)} - n\mu) h_j^{\Gamma}, \end{aligned} \quad (51)$$

$$\tilde{\mathcal{H}}_{int} = T + \frac{e}{2} \int d\mathbf{q} [\Phi(\mathbf{q}) \hat{\rho}_{-\mathbf{q}} + \hat{\rho}_{\mathbf{q}} \Phi(-\mathbf{q})] - \mathcal{H}_D. \quad (52)$$

Here

$$h_{jL,j'L'} = (jL | \frac{\hat{p}^2}{2m} + \Phi(\mathbf{r}) | j'L') \quad (53)$$

is the frequency matrix of the conduction electrons in the self-consistent field $\Phi(\mathbf{r})$. The Hamiltonian $\tilde{\mathbf{h}}$ for them can be obtained if we make a transformation to the orthogonal variables α , using the Cholesky decomposition for the overlap matrix $\mathbf{O}$:

$$\begin{aligned} \mathbf{c}^{\dagger}(\mathbf{h} - \mu \mathbf{O})\mathbf{c} &= \mathbf{c}^{\dagger}[\bar{\mathbf{Z}}(\bar{\mathbf{Z}}^{-1}\mathbf{h}\mathbf{Z}^{-1})\mathbf{Z} - \mu \bar{\mathbf{Z}}\mathbf{Z}]\mathbf{c} = \\ &(\mathbf{c}^{\dagger}\bar{\mathbf{Z}})[\tilde{\mathbf{h}} - \mu\mathbf{I}](\mathbf{Z}\mathbf{c}) = \alpha^{\dagger}[\tilde{\mathbf{h}} - \mu\mathbf{I}]\alpha. \end{aligned} \quad (54)$$

Let us now insert into $\tilde{\mathcal{H}}_{int}$ the expression for $\hat{\rho}_{\mathbf{q}}$ in the jL -representation. Taking into account that

$$\begin{aligned} \frac{e}{2} \int d\mathbf{q} \, \Phi(\mathbf{q}) \mathcal{O}_{jL,j'L'}(\mathbf{q}) &= \frac{e}{2} \int d\mathbf{r} \, \phi_{jL}^*(\mathbf{r}) \Phi(\mathbf{r}) \phi_{j'L'}(\mathbf{r}) \\ &\equiv V_{jL,j'L'} \end{aligned} \quad (55)$$

are matrix elements of the self-consistent Coulomb field, we find that $\tilde{\mathcal{H}}$ actually gives the periodic Hubbard-Anderson Hamiltonian

$$\begin{aligned}
\tilde{\mathcal{H}} = & \int d\mathbf{q} \, q^2 \Phi(\mathbf{q}) \Phi(-\mathbf{q}) \\
& + \sum (h^{LDA} - \mu \mathcal{O})_{jL,j'L'} c_{jL}^\dagger c_{j'L'} \\
& + \sum (\tilde{E}_{j\Gamma}^{(n)} - n\mu) h_j^\Gamma \\
& + \sum [V_{j\mu,j\mu'} (f_\mu^\dagger f_{\mu'})^{\xi \neq [\Gamma, \Gamma]} Z^\xi + h.c.] \\
& + \sum (\frac{p^2}{2m} + V - \mu \mathcal{O})_{jL,j'\mu'} (f_{\mu'}^a)^\dagger c_{jL}^\dagger X_{j'}^a \\
& + (\frac{p^2}{2m} + V - \mu \mathcal{O})_{j\mu,j'\mu'} (f_\mu^\dagger)^{\bar{a}} X_j^{\bar{a}} c_{j'L} \\
& + \sum (1 - \delta_{jj'}) (\frac{p^2}{2m} + V - \mu \mathcal{O})_{j\mu,j'\mu'} \\
& \times (f_\mu^\dagger)^{\bar{a}} (f_{\mu'}^b) X_{j'}^{\bar{a}} X_{j'}^b \\
& - \mathcal{H}_D.
\end{aligned} \tag{56}$$

Thus, within this approximation, the single-ion energies $\tilde{E}_{j\Gamma}^{(n)}$ are shifted by the self-consistent field of interaction with other ions, delocalized electrons and the localized ones, but belonging to other sites: $\tilde{E}_{j\Gamma}^{(n)} = E_{j\Gamma}^{(n)} + \langle \Gamma | \Phi(r) | \Gamma \rangle$. However, the self-consistent field should be found from the Poisson equation and, therefore, it contains only the Hartree part of the interaction between the collective quasi-particles. Nevertheless, this problem does not coincide with the single-particle Hartree approximation, since it contains additional information about the structure of the many-electron states $|\Gamma\rangle$ of the ion. Due to the non-linearity of the problem the approximations for the Green functions (GFs) can be used in a different form from the standard single-particle problem in the Hartree approximation. This does not only lead to different expressions for the charge density, but makes it possible to improve the approximations for the matrix elements. Thus, in spite of the fact that the static field $\Phi(\mathbf{r})$ fulfills the Poisson equation, in this approximation $V_{jLj'L'}$ does not necessarily correspond to the potential for the electrons in the Hartree approximation. Particularly, as seen from the solution of the self-consistent Anderson model, presented in Ref.¹⁶, the potential depends implicitly on the many-body population numbers of the ion states already in the lowest approximation.

The exchange contribution appears in first order between electrons via the fluctuation of

the field φ , $\propto \langle \mathcal{T} \delta\varphi(\tau) \delta\varphi(\tau') \rangle$. This study we leave for the future, however, it is interesting to note that this exchange involves also the contributions from fluctuations caused by the intra-ion transitions.

The charge density for the Poisson equation can be found from the GFs. It is clear that if it is possible to approximate this potential by a spherically symmetrical one, $V_{j\mu j\mu'} = \delta_{\mu\mu'} V_j$, then $(f_\mu^\dagger f_\mu)^\xi = \delta_{\xi, [\Gamma, \Gamma]}$ for the orbitals, μ , occupied in the state Γ . The averages $\langle c^\dagger c \rangle$, $\langle c^\dagger X \rangle$, $\langle X^\dagger c \rangle$, $\langle X^\dagger X \rangle$ needed for finding $\langle \rho(\mathbf{r}) \rangle$, can be found from the corresponding GFs.

IV. MIXING INTERACTION

Let us now rewrite the problem in a form close to the standard periodical Anderson model. This allows us to discuss different possible definitions for the matrix element of the mixing interaction. Usually the Hamiltonian of the Anderson model is written in the following form

$$\begin{aligned} \mathcal{H}^{(And)} = & \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}}^\sigma c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} + \sum_{\mathbf{k}\sigma} [V_{\mathbf{k}\mu}^\sigma e^{i\mathbf{k} \cdot \mathbf{R}_j} c_{\mathbf{k}\sigma}^\dagger f_{j\mu} + H.c.] \\ & + \sum_{j\{\mu\}} U_{\mu_1\mu_2\mu_3\mu_4} f_{j\mu_1}^\dagger f_{j\mu_2}^\dagger f_{j\mu_3} f_{j\mu_4} + \sum_{j\mu} \epsilon_\mu f_{j\mu}^\dagger f_{j\mu}. \end{aligned} \quad (57)$$

Here $\varepsilon_{\mathbf{k}}^\sigma$ is the spectrum of the conduction electrons, $V_{\mathbf{k}\mu}^\sigma$ is the matrix element of mixing interaction,

$$V_{\mathbf{k}\mu}^\sigma = \int d\mathbf{r} \phi_{\mathbf{k}}^{*\sigma}(\mathbf{r}) \left[\frac{p^2}{2m} + V(\mathbf{r}) \right] \varphi_\mu(\mathbf{r} - \mathbf{R}_j), \quad (58)$$

and $U_{\mu_1\mu_2\mu_3\mu_4}$ is the matrix elements of the Coulomb intra-shell interactions. For the mixing no problem arises in the case of the impurity Anderson model, since the potential in this case is the difference between the periodical potential for the conduction electrons and the potential of the impurity, although the local on-site term is equal to zero due to symmetry reasons, overlap with the orbitals of neighboring ions gives non-zero contribution (see the paper by Anderson¹⁷). In the case of the periodic Anderson model (PAM) this form of the matrix element suggests that either the potential has different symmetry from the Bloch

wave functions, or the functions $\phi_{\mathbf{k}}^{*\sigma}(r)$ and $\varphi_{\mu}(\mathbf{r} - \mathbf{R}_j)$ are not orthogonal. It is not clear how to fulfill the first assumption in the case of elemental metals (like Ce metal) since we are dealing with a periodic system. In the second case

$$\begin{aligned} & \int d\mathbf{r} \phi_{\mathbf{k}}^{*\sigma}(\mathbf{r}) \left[\frac{p^2}{2m} + V(\mathbf{r}) \right] \varphi_{\mu}(\mathbf{r} - \mathbf{R}_j) \\ &= \varepsilon_{\mathbf{k}}^{\sigma} \int d\mathbf{r} \phi_{\mathbf{k}}^{*\sigma}(\mathbf{r}) \varphi_{\mu}(\mathbf{r} - \mathbf{R}_j) = \varepsilon_{\mathbf{k}}^{\sigma} \mathcal{O}_{\mathbf{k}\sigma, j\mu}. \end{aligned} \quad (59)$$

Therefore, in order to have a non-zero mixing, one has to work in terms of a non-orthogonal basis set, but in this case a) there is a contribution from the chemical potential to the partition function which affects the mixing, and b) the non-orthogonality causes non-zero anticommutation relations between the f - and c -operators. This is never taken into account in model calculations.

Let us consider the consequences from our formulation. Since the mixing matrix element has a single-electron form, let us make in our saddle-point Hamiltonian a transformation that diagonalizes the conduction electrons. First we have to rewrite the Hamiltonian, Eq.(56) in $\mathbf{k}$ -space (for the formulas to be transparent, we will write them for the case of one atom in the elementary cell, then, the single-ion matrix elements and energies do not depend on the ion index). Using the definition:

$$c_{jL} = \sum_{\mathbf{k}} e^{-i\mathbf{k} \cdot \mathbf{R}_j} c_{\mathbf{k}L}, \quad c_{jL}^{\dagger} = \sum_{\mathbf{k}} e^{i\mathbf{k} \cdot \mathbf{R}_j} c_{\mathbf{k}L}^{\dagger}, \quad (60)$$

we find

$$\begin{aligned} \tilde{\mathcal{H}} = & \int d\mathbf{q} \, q^2 \Phi(\mathbf{q}) \Phi(-\mathbf{q}) \\ & + \sum [h_{L,L'}(\mathbf{k}) - \mu \mathcal{O}_{L,L'}(\mathbf{k})] c_{\mathbf{k}L}^{\dagger} c_{\mathbf{k}L'} \\ & + \sum (\tilde{E}_{\Gamma}^{(n)} - n\mu) h_j^{\Gamma} + \sum [V_{\mu,\mu'} (f_{\mu}^{\dagger} f_{\mu'})^{\xi \neq [\Gamma, \Gamma]} Z_j^{\xi} + h.c.] \\ & + \sum \left(\frac{p^2}{2m} + V - \mu \mathcal{O} \right)_{jL, j'\mu'} e^{i\mathbf{k} \cdot \mathbf{R}_j} (f_{\mu'})^a c_{\mathbf{k}L}^{\dagger} X_{j'}^a \\ & + \sum \left(\frac{p^2}{2m} + V - \mu \mathcal{O} \right)_{j\mu, j'L'} e^{-i\mathbf{k} \cdot \mathbf{R}_j} (f_{\mu}^{\dagger})^{\bar{a}} X_j^{\bar{a}} c_{\mathbf{k}L} \\ & + \sum (1 - \delta_{jj'}) \left(\frac{p^2}{2m} + V - \mu \mathcal{O} \right)_{j\mu, j'\mu'} (f_{\mu}^{\dagger})^{\bar{a}} (f_{\mu'})^b X_{j'}^{\bar{a}} X_{j'}^b \\ & - \mathcal{H}_D. \end{aligned} \quad (61)$$

Now we have to rewrite this in terms of the operators $\alpha_{\mathbf{k}\gamma} = Z_{\mathbf{k}}^{\gamma L} c_{\mathbf{k}L}$, $\alpha_{\mathbf{k}\gamma}^\dagger = c_{\mathbf{k}L}^\dagger \bar{Z}_{\mathbf{k}}^{L\gamma}$. It is easy to see that they are orthogonal to each other

$$\begin{aligned} \alpha_{\mathbf{k}\gamma} \alpha_{\mathbf{k}\gamma'}^\dagger + \alpha_{\mathbf{k}\gamma'}^\dagger \alpha_{\mathbf{k}\gamma} &= Z_{\mathbf{k}}^{\gamma L} (c_{\mathbf{k}L} c_{\mathbf{k}L'}^\dagger + c_{\mathbf{k}L'}^\dagger c_{\mathbf{k}L}) \bar{Z}_{\mathbf{k}}^{L'\gamma'} \\ &= Z_{\mathbf{k}}^{\gamma L} (\mathcal{O}^{-1})_{LL'} \bar{Z}_{\mathbf{k}}^{L'\gamma'} = Z_{\mathbf{k}}^{\gamma L} (Z_{\mathbf{k}}^{-1})^{L\gamma_1} (\bar{Z}^{-1})^{\gamma_1 L'} \bar{Z}_{\mathbf{k}}^{L'\gamma'} \\ &= \delta_{\gamma\gamma'}. \end{aligned} \quad (62)$$

$$\begin{aligned} \mathbf{c}^\dagger (\mathbf{h} - \mu \mathbf{O}) \mathbf{c} &= \mathbf{c}^\dagger [\bar{\mathbf{Z}} (\bar{\mathbf{Z}}^{-1} \mathbf{h} \mathbf{Z}^{-1}) \mathbf{Z} - \mu \bar{\mathbf{Z}} \mathbf{Z}] \mathbf{c} = \\ &= (\mathbf{c}^\dagger \bar{\mathbf{Z}}) [\tilde{\mathbf{h}} - \mu \mathbf{I}] (\mathbf{Z} \mathbf{c}) = \alpha^\dagger [\tilde{\mathbf{h}} - \mu \mathbf{I}] \alpha. \end{aligned} \quad (63)$$

Thus, we get

$$\begin{aligned} \tilde{\mathcal{H}} &= \int d\mathbf{q} \, q^2 \Phi(\mathbf{q}) \Phi(-\mathbf{q}) \\ &+ \sum [(\bar{Z}_{\mathbf{k}}^{-1})^{\gamma L} h_{L,L'}(\mathbf{k}) (Z_{\mathbf{k}}^{-1})^{L\gamma'} - \mu \delta_{\gamma\gamma'}] \alpha_{\mathbf{k}\gamma}^\dagger \alpha_{\mathbf{k}\gamma'} \\ &+ \sum (\tilde{E}_\Gamma^{(n)} - n\mu) h_j^\Gamma + \sum [V_{\mu,\mu'} (f_\mu^\dagger f_{\mu'})^{\xi \neq [\Gamma, \Gamma]} Z_j^\xi + h.c.] \\ &+ \sum (\bar{Z}^{-1})^{\gamma L} (\frac{p^2}{2m} + V - \mu \mathcal{O})_{jL,j'\mu'} e^{i\mathbf{k} \cdot \mathbf{R}_j} (f_{\mu'}^a)^\dagger \alpha_{\mathbf{k}\gamma}^\dagger X_{j'}^a \\ &+ \sum (\frac{p^2}{2m} + V - \mu \mathcal{O})_{j\mu,j'L} (Z_{\mathbf{k}}^{-1})^{L\gamma} (f_\mu^\dagger)^{\bar{a}} e^{-i\mathbf{k} \cdot \mathbf{R}_j} X_j^{\bar{a}} \alpha_{\mathbf{k}\gamma} \\ &+ \sum (1 - \delta_{jj'}) (\frac{p^2}{2m} + V - \mu \mathcal{O})_{j\mu,j'\mu'} (f_\mu^\dagger)^{\bar{a}} (f_{\mu'}^b) X_j^{\bar{a}} X_{j'}^b \\ &- \mathcal{H}_D. \end{aligned} \quad (64)$$

At last, diagonalizing the conduction electron Hamiltonian $\bar{\mathbf{Z}}^{-1} \mathbf{h} \mathbf{Z}^{-1}$, we have

$$\begin{aligned} \tilde{\mathcal{H}} &= \int d\mathbf{q} \, q^2 \Phi(\mathbf{q}) \Phi(-\mathbf{q}) + \sum [\varepsilon_{\mathbf{k}\lambda} - \mu] \tilde{c}_{\mathbf{k}\lambda}^\dagger \tilde{c}_{\mathbf{k}\lambda} \\ &+ \sum (\tilde{E}_\Gamma^{(n)} - n\mu) h_j^\Gamma + \sum [V_{\mu,\mu'} (f_\mu^\dagger f_{\mu'})^{\xi \neq [\Gamma, \Gamma]} Z_j^\xi + h.c.] \\ &+ \sum V_\lambda^{\bar{a}}(k) e^{i\mathbf{k} \cdot \mathbf{R}_j} \tilde{c}_{\mathbf{k}\lambda}^\dagger X_{j'}^a \\ &+ \sum e^{-i\mathbf{k} \cdot \mathbf{R}_j} X_j^{\bar{a}} \alpha_{\mathbf{k}\gamma} \\ &+ \sum (1 - \delta_{jj'}) (\frac{p^2}{2m} + V - \mu \mathcal{O})_{j\mu,j'\mu'} (f_\mu^\dagger)^{\bar{a}} (f_{\mu'}^b) X_j^{\bar{a}} X_{j'}^b \\ &- \mathcal{H}_D, \end{aligned} \quad (65)$$

where the band energy and mixing matrix elements are

$$\varepsilon_{\mathbf{k}\lambda} = \vartheta_{\gamma}^{*\lambda}(\mathbf{k})(\bar{Z}_{\mathbf{k}}^{-1})^{\gamma L} h_{L,L'}(\mathbf{k})(Z_{\mathbf{k}}^{-1})^{L\gamma'} \vartheta_{\gamma'}^{\lambda}(\mathbf{k}), \quad (66)$$

$$\begin{aligned} V_{\lambda}^{\bar{a}}(\mathbf{k}) &= \vartheta_{\gamma}^{*\lambda}(\mathbf{k})(\bar{Z}^{-1})^{\gamma L} \left(\frac{p^2}{2m} + V - \mu \mathcal{O} \right)_{jL,j'\mu'} (f_{\mu'}^{\lambda})^a \\ &\equiv v_{\mu'}^{\lambda}(\mathbf{k})(f_{\mu'}^{\lambda})^a, \end{aligned} \quad (67)$$

$$\begin{aligned} V_{\lambda}^{*\bar{a}}(\mathbf{k}) &= \left(\frac{p^2}{2m} + V - \mu \mathcal{O} \right)_{j\mu,j'L} (Z_{\mathbf{k}}^{-1})^{L\gamma} \theta_{\gamma}^{\lambda}(\mathbf{k})(f_{\mu}^{\dagger})^{\bar{a}} \\ &\equiv (f_{\mu}^{\dagger})^{\bar{a}} v_{\mu'}^{*\lambda}(\mathbf{k}), \end{aligned} \quad (68)$$

where $\{\vartheta\}$ diagonalizes $\bar{\mathbf{Z}}^{-1}\mathbf{h}\mathbf{Z}^{-1}$, and v_i^{λ} is the one-electron hybridization parameter. Thus, the matrix element of the mixing interaction has to be found self-consistently together with the charge density (which in turn depends on the particular approximation in which the PAM is solved) and can be represented in the form of a sum over all localized orbitals of products of the matrix element of the single-particle potential (on the conduction electron Bloch function $\phi_{k\lambda}(\mathbf{r})$ and the localized orbital $\chi_{\mu}(\mathbf{r})$) and the factor $(f_{\mu'}^{\lambda})^a$, which reflects the contribution of this orbital into Fermion-like transition. Irkhin¹⁵ has performed the calculation of this factor for the $4f$ -elements making use of the Racah technique leaving, the single-particle matrix element undefined. Putting $\bar{a} = \bar{a}(\Gamma_n, \Gamma_{n-1})$ and $\mu = (l, m, \sigma)$ and using the result of the calculation of Irkhin, we can write these coefficients as follows

$$\begin{aligned} (f_{\mu}^{\dagger})^{\bar{a}} &= \langle \Gamma_n | f_{lm\sigma}^{\dagger} | \Gamma_{n-1} \rangle \\ &= \sqrt{n[\Gamma_n][\Gamma_{n+1}]} \begin{Bmatrix} S_n & L_n & J_n \\ S_{n-1} & L_{n-1} & J_{n-1} \\ 1/2 & l & j \end{Bmatrix} G_{\Gamma_{n-1}}^{\Gamma_n}, \end{aligned} \quad (69)$$

where $\gamma = (lm_l\sigma)$ are the one-electron quantum numbers, $[a] = 2a + 1$ and $G_{\Gamma_{n-1}}^{\Gamma_n}$ is the parentage Racah coefficients and $j = l + 1/2$. The coefficients $(f_{\mu}^{\dagger})^{\bar{a}}$ are different for the two channels, $j = 5/2$ and $j = 7/2$. The square of them are given in Table. I.

TABLE I. Coefficients for the mixing interaction for many-body states. For the f -series, taken from¹⁵.

However, there are more considerations to the problem, since the Bloch orbitals are not orthogonal to the localized orbitals. In the equation of motion for the operators appear combinations involving the overlap matrices. For the Hamiltonian which includes hopping and mixing interactions (the periodic Hubbard-Anderson model) the diagram technique and different approximations for the Green functions (GF) are given in I, while the full self-consistent solution for rare earths in the simplest possible approximation is presented in Ref.¹⁶.

V. DISCUSSION

Many different suggestions exists in the literature on how the parameters of the Anderson Hamiltonian (periodical or impurity) should be calculated from an *ab initio* approach and a consensus is not yet achieved. This motivated us to make an attempt to derive the parameters from a total Hamiltonian. Since the Anderson model is usually used for the description of the cases when strong electron correlations are well developed, it is reasonable to consider strong intra-atomic Coulomb interactions first. For this reason we have performed a derivation of the self-consistent PAM in four steps: i) first we separate, in the Hamiltonian, the strong intra-atomic interactions and approximately diagonalized them with the help of many-electron functions describing different ion terms; ii) we expressed all operators, describing *f*- and core electrons in terms of Hubbard operators; iii) we performed the Hubbard-Stratanovich decoupling of the Coulomb interaction and finally iv) we found the equation for the electric potential in a saddle-point approximation. This lead us to the effective Hamiltonian, which coincide with the generalized PAM.

All three operations before making the saddle-point approximation are exact. However, the saddle-point approximation neglects the contributions from the exchange interaction for the delocalized particles (excitations) and Coulomb screening effects, which appear only in the next orders with respect to fluctuations of this field near its saddle-point value. Thus, we may conclude that from this point of view this model is quite rough. On the other hand, the

way suggested here has an obvious advantage compared to the PAM with non-self-consistent parameters since it, at least, takes care about perturbations of the local charge density which may introduce quite large changes in energy.
